CASE REPORT

A 65-year-old Indian housewife, P5L5, married since 40 years, postmenopausal since 20 years, weighing 65 kg, came to our outpatient department in March 2015 with complaints of a gradually increasing huge abdominal swelling which she had noticed 6 months back. The swelling was accompanied with dull aching pain in the lower back. She also complained of breathlessness, insidious in onset, which worsened on recumbency leading to decreased sleep. She had the sensation of fullness of abdomen, leading to decreased appetite. She also complained of incomplete voiding of urine and usually remained constipated. There was a history of generalized weakness. There was no history of vomiting or other gastrointestinal disturbances, colicky pain or fainting attacks. The patient had no history of the previous medial or surgical illnesses. There was no family history of malignancies. Despite all these symptoms, the patient did not seek for medical attention earlier owing to low socioeconomic status. It was only when she started having decreased appetite that her relatives brought her to the hospital.

The patient was found to be averagely built, weighing 65 kg. Physical examination revealed pale skin; the patient was afebrile with a pulse rate of 78 b/min, blood pressure of 128/66 mm Hg and respiratory rate of 22 cycles/min. Her abdomen was distended, and tense with an abdominal girth
of 125 cm with a dull note on percussion and presence of superficial dilated veins. Plain radiograph of the chest (P-A view) was within normal limits. CA-125 was 31.3 IU/ml.

An ultrasound done suggested a large well-defined cystic lesion of about 32 cm × 35 cm × 28 cm arising from pelvis, reaching up to the epigastrium, displacing liver and spleen supero-laterally, and kidneys posteriorly and bowel loops peripherally. On Doppler, septa did not show vascularity. Peripheral low impedance with continuous vascularity was present. Uterus was seen separately. Ovaries were not seen separately.

Multiple detector computed tomography scan of abdomen and pelvis (plain + contrast) (Figure 1) was suggestive of a large cystic lesion with thin internal enhancing septations in abdomen and pelvis measuring approximately 25.4 cm × 27.1 cm × 27.5 cm. The right ovary was not seen separately from this lesion. Superiorly the lesion reached up to subhepatic region. Displacement of small bowel loops with compression of inferior vena cava (IVC) and left renal vein was seen. Left ovary measuring 32 mm × 26 mm with internal calcifications seen. CA-125 was 31.3 IU/ml.

Exploratory laparotomy was done. A huge multicystic tumor arising from the right ovary was seen occupying the abdomen, from the pelvis up to the diaphragm. The cyst was multiloculated, and tumor was seen displacing spleen, liver and bowel loops. The extent of the tumor was identified (Figure 2). Gross evidence of malignancy was ruled out. Decompression of the cyst was done by controlled drainage of 4 liters of fluid intra-operatively after which the tumor measuring 29 cm × 28 15 cm and weighing 7 kg was removed en bloc. Total abdominal hysterectomy along with bilateral salpingo-oophorectomy and partial omentectomy was done. Lymph nodes were not involved. The left ovary was seen measuring 3 cm × 2 cm. An abdominal drain was placed in situ for 3 days (Figure 3).

The post-operative period was uneventful. Patient weighed 55 kg on day 7 post operation. Histopathological examination revealed serous cystadenoma of the ovary.

**DISCUSSION**

In a women’s lifetime, ovarian tumors can present at any age. The size of an ovarian cyst can range from a small ping pong ball to a mass larger than a full term pregnancy.
The definition of large ovarian cysts varies from those measuring more than 10 cm in diameter in preoperative scans to those reaching above the umbilicus. On the basis of cell of origin, ovarian neoplasms are divided into epithelial, stromal and germ cell neoplasms. Ovarian epithelial tumors constitute about half of all the ovarian tumors. Of these, 40% constitute benign tumors and 86% constitute malignant tumors. Benign serous tumors comprise 25% benign ovarian neoplasms and 58% ovarian serous tumors. Depending on the age, 70% serous tumors are benign, about 10% have borderline malignant potential and about 20% are malignant. Serous tumors are bilateral in 10% cases. The epithelium of cysts is cylindrical and mono- or multi-stratified. Cuboidal epithelium occurs due to the pressure inside the cyst. These cells have clear cytoplasm with the hyperchromatic nucleus at the base. Cancer antigen (CA)-125 helps in identifying and following malignant epithelial tumors of the ovary. Cystadenomas are thin walled cysts, containing serum like fluid. Some papillary projections might appear on the internal surface of the cyst. Usually, serous cystadenomas are multicellular. In approximately 25% cases of ovarian serous cystadenoma, some evidence of estrogenic activity has been found. 44% cases of serous cystadenoma present with postmenopausal bleeding and 73% have an abnormally high cornification index. Tumors arise from within the pelvis, and patients commonly seek medical aid at advanced stages. In the year 1922, Spohn reported a large ovarian cyst weighing 148.6 kg which are possibly the largest. Many intra-operative complications occur during surgical removal of large ovarian tumors. Crossen and Crossen reported splanchic dilatation and venous pooling after the sudden removal of large intra-abdominal masses. Howard et al. showed that hypotension can occur due to decreased venous return resulting from obstructed IVCI. Poulias and Prombonas showed that sudden re-expansion of a chronically collapsed lung, which occurred due compression by the elevated abdomen might result in pulmonary oedema.

Various imaging modalities are used in making a diagnosis of ovarian tumors. Ultrasonography is used to diagnose and infer about possible malignancy. Computed tomography and magnetic resonance imaging scans can be used for larger masses and metastatic involvement. Serial measurements of the biomarker CA-125 can be of great help. Surgery is inevitable for large tumors even if benign. Surgical management includes excision. The contralateral ovary should also be examined. Hunter et al. reported that rupture of the cyst capsule and greater dissemination can be prevented by gradual decompression. Repeated paracentesis have been associated with tumor seeding of the peritoneal cavity, bleeding, infection, and increased adhesions resulting in difficult cyst removal.

**CONCLUSION**

In developing countries, patients having ovarian tumors seek medical help usually during advanced stages of the disease. Fortunately in our case, the tumor was removed successfully without any dissemination despite a delay in diagnosis. Reporting such cases with unusual presentations helps to increase the suspicion of its possibility and avoid any misdiagnosis or improper treatment and its complications.
