Abstract

Background: Cholecystectomy is the most commonly performed surgery for gallbladder (GB) diseases. Presently Laparoscopic Cholecystectomy is performed routinely due its advantages over Open Cholecystectomy. However in certain conditions conversion to Open Cholecystectomy is required. Knowledge regarding the underlying reasons for conversion could help surgeons during pre-operative assessment and obtain consent of patients with all information provided to them about the conversion to be done if required so that they could have adequate psychological preparation and planning of convalescence. The prediction of a high risk of conversion or a difficult laparoscopic procedure would also allow efficient and appropriate arrangement of the operating schedule and the availability of experienced laparoscopic surgeons for the procedure. It would also allow an earlier intra-operative decision to convert if difficulty is encountered.

Study Design: The study design is of case series.

Aim of the Study: The aim is to study and identify the risk factors for conversion of LC to OC in Indian conditions (Telangana) and to determine the predictive factors of conversion in patients undergoing LC.

Results: This study was done prospectively over a period of 2 years, from September 2014 to September 2016, among 206 patients who underwent LC for symptomatic GB disease in all Surgical Units of Mahatma Gandhi Memorial Hospital, Warangal. Among the 206 patients in the study, 23 (11.16%) patients were converted to OC. The most common reasons for conversion are severe adhesions caused by tissue inflammation (12 patients [52%]) and inability to define anatomy due to fibrosis of Calot’s triangle (5 patients [21.7%]). Conversion to OC due to intraoperative hemorrhage occurred in three patients. Conversion was enforced due to uncontrolled bleeding from GB bed in one patient (4.35%), which occurred during diathermic dissection of GB. In another two patients (8.7%), there was uncontrolled bleeding from Calot’s triangle, which occurred during dissection of cystic duct and artery. Conversion to OC was required to achieve successful hemostasis, as they could not be controlled laparoscopically. Conversion to OC caused by injury of the common bile duct (CBD) occurred in one patient (4.35%), and the injury is identified intraoperatively and repaired over a T-tube. In one patient (4.35%), conversion to OC was required to perform CBD exploration for suspected choledocholithiasis, based on laparoscopic finding of dilated CBD; pre-operative liver function tests (LFTs) and ultrasound were normal in this patient, and intraoperative OC facility was unavailable. Conversion to OC occurred due to equipment failure in one patient (4.35%). Conversion was due to inability to establish and/or maintain sufficient pneumoperitoneum during the course of LC and due to clip applicator failure.

Conclusions: (1) In this study, the following factors are identified as significant risk factors for conversion of LC to open cholecystectomy. (i) Advanced age (>60 years), (ii) obesity (body mass index >27.5 kg/m²), (iii) leukocytosis, (iv) abnormal LFT; ultrasonography findings (1) thickened GB wall >4 mm, (2) evidence of pericholecystic fluid; (v) LC done in emergency setting for acute cholecystitis; no significant risk factors: (a) Gender, (b) previous upper abdominal surgery, (c) comorbidities; (2) In patients with these risk factors, management can be improved by (i) pre-operative counseling of the patient regarding these risk factors and high chances of conversion and (ii) early conversion to OC.

Key words: Laparoscopic cholecystectomy, Conversion, Open cholecystectomy cholelithiasis
INTRODUCTION

Biliary diseases constitute a major portion of digestive tract disorders. Among these, gallstone disease is the most common biliary pathology. Cholecystectomy is the most commonly performed surgery for gallbladder (GB) diseases. Alternative treatments such as chemical dissolution, percutaneous extraction, and ultrasonic lithotripsy have been tried. Although these methods are minimally invasive, most individuals require subsequent therapy for recurrent symptoms. Due to the frequency of recurrent calculi after stone removal alone, cholecystectomy remains the standard therapy. Carl–Langenbucher formed the first ever open cholecystectomy (OC) on July 15, 1882, in Berlin on a 42-year-old man. The most common complications that occur after cholecystectomy are post-operative ileus, atelectasis, and wound infection; other rare complications include pulmonary embolus, pneumonia, myocardial infarction, biliary peritonitis, subphrenic abscess, bacterial peritonitis, and delayed hemorrhage, due to which patients are hospitalized for several days and disabled from normal activity for several months in a year. In an attempt to reduce morbidity and disability, OC has been replaced by minimally invasive laparoscopic cholecystectomy (LC). LC was first performed in March 1987 by Philippe Moret in Lyon, France, a revolution in the treatment of cholelithiasis. Since the National Institutes of Health Consensus Conference in 1993, LC has replaced OC as the standard treatment in patients with symptomatic cholelithiasis. In the last decade, more than 90% of cholecystectomies were performed laparoscopically due to its advantages such as decreased post-operative pain and ileus, shorter hospital stay, earlier return to normal activity, earlier oral intake, and improved cosmetic result over OC. However, there is still a substantial proportion of patients who need OC such as patients with severe cardiac disease, pulmonary disease, concomitant disease, multiple previous abdominal incisions and in whom LC cannot be successfully performed, and conversion to open surgery is required because of technical difficulties, to avoid or repair intra-operative injury, not clearly visualized anatomic relationships, or to treat associated conditions.

Conversion to OC has been associated with an increased overall morbidity, surgical site and pulmonary infections, longer hospital stays, increased total cost, and dissatisfaction of the patients. Knowledge regarding the underlying reasons for conversion could help surgeons during pre-operative assessment and obtain consent of patients with all information provided to them about the conversion to be done if required so that they could have adequate psychological preparation and planning of convalescence.

The prediction of a high risk of conversion or a difficult laparoscopic procedure would also allow efficient and appropriate arrangement of the operating schedule and the availability of experienced laparoscopic surgeons for the procedure. It would also allow an earlier intra-operative decision to convert if difficulty is encountered.

METHODOLOGY

Inclusion Criteria

The inclusion criteria were as follows: All patients with symptomatic cholelithiasis, ultrasound (US) abdomen demonstrating cholelithiasis and normal common bile duct (CBD) and patients with a calculous cholecystitis.

Exclusion Criteria

Patients with severe heart and/or pulmonary diseases, concomitant disease requiring open surgery, or multiple previous upper abdominal incisions and patients who were not willing for surgery were excluded from the study. The total number of cases were 206.

All the patients (n = 206) selected as per the criteria from September 2014 to September 2016 were admitted in the surgical unit of Mahatma Gandhi Memorial Hospital, Kakatiya Medical College, Warangal, Telangana State, India, after ethical committee approval and patient consent.

The variables recorded and studied in this study are as follows:

- Sex,
- Age,
- Obesity,
- History of previous upper abdominal surgeries,
- Comorbid illnesses (chronic obstructive pulmonary disease, ischemic heart disease, hypertension, chronic renal failure, and diabetes),
- The surgery setting (emergency or elective),
- White blood cell (WBC) count,
- Serum total bilirubin, and
- Sonographic findings, including GB wall thickness, pericholecystic fluid, CBD stone, and CBD diameter,
- Operative details such as operation time,
- Causes for the conversion to open surgery.

Cholecystitis was diagnosed by clinical and laboratory assessments and radiological report. Patients who presented with acute cholecystitis in the 1st 72 h underwent emergency LC. The patients whose radiological results did not support the clinical and laboratory data were not considered to have acute cholecystitis. If the patients with acute...
infection were admitted more than 72 h after the onset of symptoms, elective LC was carried out 8–10 weeks later following a course of conservative treatment (delayed cholecystectomy). Obesity was defined as body mass index (BMI) above the cutoff value of 27.5 (kg/m²).

A patient was categorized as having comorbidity when at least one of the following conditions was present at the time of cholecystectomy:

- Diabetes mellitus,
- Hypertension,
- Myocardial infarction,
- Congestive heart failure or
- Chronic obstructive pulmonary disease,
- Chronic renal failure.

LC was performed by experienced surgeons and surgical residents under supervision. The operation was performed using a four-port technique, with the surgeon standing on the left side of the patient. Veress needle insertion was attempted in all patients. Minimal diathermy was used to dissect a critical view of safety. Method of dissecting the GB from the liver bed, using the diathermy spatula or hook, was left to the preference of the surgeon. Conversion to OC was performed through a right subcostal incision. The cystic artery and cystic duct were ligated separately. The duration of operation was taken from the time of the initial skin incision to the time of skin closure. The post-operative duration of hospital stay was taken as the number of nights the patient stayed in the hospital after the procedure. Total patients in this study are divided into two groups based on completion of LC. One group is LC-completed group and the other one is LC converted to OC group.

**RESULTS**

This study was done prospectively over a period of 2 years, from September 2014 to September 2016, including 206 patients who underwent LC for symptomatic GB disease in all Surgical Units of Mahatma Gandhi Memorial Hospital, Warangal. Among the 206 patients in the study, 23 (11.16%) patients were converted to OC.

The most common reasons for conversion are severe adhesions caused by tissue inflammation (12 patients [52%]) and inability to define anatomy due to fibrosis of Calot’s triangle (5 patients [21.7%]).

Conversion to OC due to intraoperative hemorrhage occurred in three patients. Conversion was enforced due to uncontrolled bleeding from GB bed in one patient (4.35%), which occurred during diathermic dissection of GB. In another two patients (8.7%), there was uncontrolled bleeding from Calot’s triangle, which occurred during dissection of cystic duct and artery.

Conversion to OC was required to achieve successful hemostasis, as they could not be controlled laparoscopically.

Conversion to OC caused by injury of the CBD occurred in one patient (4.35%), and the injury is identified intraoperatively and repaired over a T-tube.

In one patient (4.35%), conversion to OC was required to perform CBD exploration for suspected choledocholithiasis, based on laparoscopic finding of dilated CBD; pre-operative liver function tests (LFTs) and US were normal in this patient and there was no intraoperative OC facility available.

Conversion was due to an inability to establish and/or maintain sufficient pneumoperitoneum during the course of LC and due to clip applicator failure.

**Gender**

Of the 206 patients in the study, 145 were female and 61 were male. Successful LC was performed in 131 females and 52 males, whereas conversion was required in 14 females (9.7%) and 9 males (14.8%).

**Age**

In this study, patients aged under 60 years constituted 177 and over 60 years constituted 29; successful LC was performed in 161 patients aged under 60 years and 22 patients over 60 years, whereas conversion was required in 16 (9.03%) patients aged under 60 years and in 7 (24.1%) patients over 60 years.

**BMI**

In this study, out of 140 non-obese patients, 130 are in LC-completed group and 10 (7.14%) in converted group. Out of 66 obese patients, 53 are in LC-completed group and 13 (19.7%) in converted group.

**Previous Upper Abdominal Surgery**

In this study, five patients had upper abdominal scar, of these three patients were in LC-completed group and

GB: Gallbladder
2 (40%) were in converted group. A total of 201 patients had no upper abdominal scar, of these, 180 patients were in LC-completed group and 21 (10.44%) were in converted group.

Comorbidity
Sixty-four patients had comorbidity, of these 55 were in LC-completed group and 9 (14.06%) were in converted group. One hundred and forty-two patients were without comorbidity, of these 128 were in LC-completed group and 14 (9.85%) were in converted group.

Leukocytosis
In this study, 22 patients had elevated WBC, out of these, 16 were in LC-completed group and 6 (27.3%) were in converted group. About 184 patients had normal WBC, out of these, 167 were in LC-completed group and 17 (9.2%) were in converted group.

Abnormal LFT
Among the 206 patients in this study, 18 patients had abnormal LFT, of these, 5 (27.8%) were converted to OC. About 188 patients had normal LFT, of these 18 (9.57%) were in converted group.

Ultrasoundography (USG) Findings
In this study, 66 patients had thickened GB wall, of these 13 (19.7%) patients were in converted group. About 140 patients had normal GB wall thickness, of these 10 (7.14%) were in converted group.

Pericholecystitis
In this study, pericholecystitis was found in 7 patients, of these 3 (42.9%) were in converted group. About 199 patients were without pericholecystitis, of these 20 (10.05%) were in converted group.

Surgery Setting: Emergency or Elective
Among the 206 patients in the study, chronic cholecystitis was found in 187 patients and acute cholecystitis in 19 patients. Emergency LC for acute cholecystitis was done in 19 patients, of these 5 (26.3%) required conversion. Elective LC in 187 patients with cholecystitis was done of these 18 (9.62%) required conversion.

CONCLUSION
In this study, the following factors were identified as significant risk factors for conversion of LC to open cholecystectomy: (i) Advanced age (>60 years), (ii) obesity (BMI >27.5 kg/m²), (iii) leukocytosis, (iv) abnormal LFTs; USG findings (1) thickened GB wall >4 mm, (2) Evidence of pericholecystic fluid; (v) LC done in emergency setting for acute cholecystitis; no significant risk factors: (a) Gender, (b) previous upper abdominal surgery, (c) comorbidities, (2) In patients with these risk factors, management can be improved by (i). Pre-operative counseling of the patient regarding these risk factors and high chances of conversion and (ii) early conversion to OC.
